We use neutron scattering to study the electron-doped superconducting NaFe_{0.985}Co_{0.015}As ($T_c = 14$ K), which has coexisting static antiferromagnetic (AF) order ($T_N = 31$ K) and exhibits two neutron spin resonances ($E_{r1} \approx 3.5$ meV and $E_{r2} \approx 6$ meV) at the in-plane AF ordering wave vector $\mathbf{Q}_{AF} = \mathbf{Q}_1 = (1,0)$ in reciprocal space. In the twinned state below the tetragonal-to-orthorhombic structural transition T_s , both resonance modes appear at \mathbf{Q}_1 but cannot be distinguished from $\mathbf{Q}_2 = (0,1)$. By detwinning the single crystal with uniaxial pressure along the orthorhombic *b* axis, we find that both resonances appear only at \mathbf{Q}_1 with vanishing intensity at \mathbf{Q}_2 . Since electronic bands of the orbital d_{xz} and d_{yz} characters split below T_s with the d_{xz} band sinking ~10 meV below the Fermi surface, our results indicate that the neutron spin resonances in NaFe_{0.985}Co_{0.015}As arise mostly from quasiparticle excitations between the hole and electron Fermi surfaces with the d_{yz} orbital character.

DOI: 10.1103/PhysRevB.95.094519

Understanding the role of magnetism in the electron pairing of unconventional superconductors such as copper oxides, iron pnictides, and heavy Fermions continues to be an important topic in modern condensed matter physics because superconductivity in these materials is derived from parent compounds with long-range antiferromagnetic (AF) order [1-4]. One of the key evidences suggesting that magnetism is involved in the electron pairing and superconductivity is the observation by inelastic neutron scattering (INS) of a neutron spin resonance in the superconducting state of various unconventional superconductors [5-16]. The resonance is a collective magnetic excitation occurring below the superconducting transition temperature T_c with a temperature dependence similar to the superconducting order parameter, and is located at the AF ordering wave vector \mathbf{Q}_{AF} of the parent compound [5–16]. Moreover, the energy of the resonance has been associated with T_c or superconducting gap size Δ [17,18]. In iron pnictide superconductors [Fig. 1(a)], the resonance is generally interpreted as a spin exciton arising from sign-reversed quasiparticle excitations between the hole (at Γ point) and electron (at X and Y points) Fermi surfaces [Fig. 1(b)] [19,20]. In reciprocal space, the Γ -X and Γ -Y Fermi surface nesting corresponds to wave vectors of $\mathbf{Q}_1 = (1,0)$ and $\mathbf{Q}_2 = (0,1)$, respectively [Fig. 1(c)]. If this is indeed the case, one would expect that significant modifications of the Fermi surfaces should affect the wave-vector dependence and energy of the resonance [3].

In electron-doped superconducting NaFe_{1-x}Co_xAs [Fig. 1(a)] [21–24], INS experiments have mapped out the Co-doping dependence of the resonance [11–13]. For underdoped NaFe_{0.985} Co_{0.015} As with $T_c = 14$ K and

a tetragonal-to-orthorhombic structural transition below $T_s \approx 40$ K, where the static long-range AF order ($T_N = 31$ K) microscopically coexists with superconductivity [12,25–27], superconductivity induces a dispersive sharp resonance near $E_{r1} = 3.5$ meV and a broad dispersionless mode at $E_{r2} =$ 6 meV at a wave vector consistent with $\mathbf{Q}_{AF} = \mathbf{Q}_1 = (1,0)$ but cannot be distinguished from $\mathbf{Q}_2 = (0,1)$ [12]. Although nuclear magnetic resonance (NMR) measurements on $NaFe_{1-x} Co_x As$ suggested the presence of an 8% volume fraction paramagnetic phase for x < 0.0175 samples that is doping independent [27], the bulk nature of neutron scattering does not allow us to separate this phase from the dominant AF phase. Upon further Co doping to reach optimal superconductivity without static AF order, the double resonances in NaFe_{1-x} Co_x As become a single resonance [11–13]. Since the disappearance of the double resonances occurs at approximately the same doping level as the vanishing static AF order with increasing Co doping [11–13], the presence of double resonances has been interpreted as due to the coexisting AF order and superconductivity [28,29]. In this picture, one would expect that the resonance associated with the AF order to exclusively appear at $\mathbf{Q}_{AF} = \mathbf{Q}_1 = (1,0)$ in a completely detwinned sample as the collinear AF order explicitly breaks the C_4 rotational symmetry of the orthorhombic lattice [see inset of Fig. 1(a)], while the resonance associated with itinerant electrons and simple nested Fermi surfaces (without considering the inter- and intraorbital scattering processes) should be present at both $\mathbf{Q}_{AF} = \mathbf{Q}_1$ and $\mathbf{Q} = \mathbf{Q}_2$ [Fig. 1(b)] [28,29].

Alternatively, the presence of double resonances can arise from orbital-selective pairing-induced superconducting gap anisotropy [30]. From angle resolved photoemission spectroscopy (ARPES) experiments [31–33], it was found

^{*}pdai@rice.edu

FIG. 1. (a) The phase diagram of NaFe_{1-x}Co_xAs with the arrow indicating the Co-doping concentration in our experiment. The inset shows positions of magnetic excitations in the [H, K] plane under uniaxial pressure along the *b* axis. (b) Schematic Fermi surfaces of NaFe_{0.985}Co_{0.015}As in the paramagnetic tetragonal state and different orbitals are characterized with different colors. The arrows mark nesting wave vectors $\mathbf{Q}_1 = (1,0)$ and $\mathbf{Q}_2 = (0,1)$. (c) Schematic d_{yz} and d_{xz} orbital bands in NaFe_{1-x}Co_xAs above and below T_s as seen by ARPES [31,32].

that the superconducting gap anisotropy appearing in the low Co-doping regime of $NaFe_{1-x}Co_xAs$ disappears in electron overdoped NaFe_{0.955}Co_{0.045}As [34,35]. The double resonances at $\mathbf{Q}_{AF} = \mathbf{Q}_1$ in underdoped NaFe_{1-x}Co_xAs can therefore be due to the presence of superconducting gap anisotropy in the underdoped regime [12]. Since AF order is not expected to affect the superconducting gap anisotropy, one would expect the presence of the double resonances at $\mathbf{Q}_{AF} = \mathbf{Q}_1$ and $\mathbf{Q} = \mathbf{Q}_2$ in a detwinned single crystal of NaFe_{0.985}Co_{0.015}As [30]. Therefore, by using uniaxial pressure to detwin the single crystal [36–39], one can potentially determine the microscopic origin of the double resonances [40]. In previous INS experiment on partially detwinned NaFe_{0.985}Co_{0.015}As, it was reported that the double resonance is present with similar intensity at both $\mathbf{Q}_{AF} = \mathbf{Q}_1$ and $\mathbf{Q} = \mathbf{Q}_2$, thus suggesting that the double resonance originates from the anisotropic superconducting gap in the underdoped regime [40]. However, the detwinning ratio of the studied compound was estimated from two separate experiments under possibly different pressure conditions. In addition, due to the large background level at the elastic scattering channel originated from the pressure device in the experiment, the reported detwinning ratio in Ref. [40] is likely to be overestimated. Therefore, to conclusively determine the effect of detwinning and uniaxial pressure on the resonance, one needs to carry out INS experiments by comparing directly pressured and pressureless cases using the same sample holder with the same spectrometer setup.

If we assume that low-energy spin excitations in iron pnictides originate from quasiparticle excitations between hole and electron Fermi surfaces [Fig. 1(b)], the orbital characters of hole and electron Fermi surfaces should determine the nature of observed spin excitations at Q_1 and Q_2 [19,20]. For example, INS experiments on the $LiFe_{1-x}Co_xAs$ system reveal that transverse incommensurate spin excitations observed in superconducting LiFeAs [41,42] change to commensurate spin excitations for nonsuperconducting LiFe_{0.88}Co_{0.12}As arising mostly from the hole-electron Fermi surface nesting of the d_{xy} orbitals, thus suggesting that Fermi surface nesting conditions of the d_{yz} and d_{xz} orbitals are important for superconductivity [43]. In the case of NaFe_{1-x}Co_xAs [21–24], ARPES measurements on uniaxial pressure detwinned single crystals reveal the splitting of the d_{xz} and d_{yz} orbitals at temperatures below T_s (although in case of large pressure, the splitting actually first takes place at temperatures above T_s), where the bands of dominant d_{yz} orbital character shift up in the Γ -X direction (\mathbf{Q}_1) and bands of dominant d_{xz} orbital character sink below Fermi surface in the Γ -Y direction (**Q**₂) [Fig. 1(c)] [31,32]. This means that low-energy spin excitations at wave vectors \mathbf{Q}_1 and \mathbf{Q}_2 should behave differently in the low-temperature superconducting state. Since bands of dominant d_{yz} orbital characters sink below Fermi surface below T_s , neutron spin resonance associated with quasiparticle excitations of hole-electron Fermi surfaces of the d_{yz} orbitals at \mathbf{Q}_2 should be absent below T_c , while the resonance associated with d_{yz} and d_{xy} orbitals should appear below T_c at \mathbf{Q}_1 [Figs. 1(b) and 1(c)].

To test if this is indeed the case, we carried out INS experiments on uniaxial detwinned NaFe_{0.985}Co_{0.015}As single crystal. Compared with earlier experiments on the same doping concentration [40], the new measurements have much better statistics and collected uniaxial pressured/pressureless data using the same experimental setup. We find the presence of double resonance at Q_1 and Q_2 agreeing well with the detwinning ratio obtained using magnetic Bragg peaks at these two wave vectors. These results therefore indicate that superconductivity induced resonance arises from the nesting of hole-electron Fermi surfaces with dominant d_{yz} orbital characters.

Our neutron scattering experiment was carried out on the IN8-Thermal neutron three-axis spectrometer at Institut Laue-Langevin, Grenoble, France. We used doubly focused pyrolytic graphite [PG(002)] monochromator and analyzer with fixed scattered (final) energy $E_f = 14.68$ meV. The high-order harmonics from the PG(002) monochromator are suppressed by an oriented PG filter in the scattered beam. Using a structural orthorhombic unit cell with lattice parameters $a \approx b \approx 5.5968$ Å and $c \approx 6.9561$ Å at T = 1.5 K, we denote the momentum transfer $\mathbf{Q} = H\mathbf{a}^* + K\mathbf{b}^* + L\mathbf{c}^*$ as $\mathbf{Q} = (H, K, L)$ in reciprocal lattice units (r.l.u.) with $\mathbf{a}^* =$ $\hat{\mathbf{a}}2\pi/a, \mathbf{b}^* = \hat{\mathbf{b}}2\pi/b$, and $\mathbf{c}^* = \hat{\mathbf{c}}2\pi/c$. In the AF ordered state of a completely detwinned sample with uniaxial pressure applied along the *b*-axis direction, AF Bragg peaks occur at Q = (1,0,L) with L = 0.5, 1.5, 2.5... and there are no magnetic peaks at (0,1,L) [22].

High-quality NaFe_{0.985}Co_{0.015}As single crystals are prepared by the self-flux method [44], and we cut one large single crystal (~300 mg) into a rectangular shape along the [1,0,0] and [0,1,0] directions. The sample is mounted inside an aluminum-based sample holder with a uniaxial pressure of $P \approx 10$ MPa along the *b*-axis direction (although it is

FIG. 2. (a) Temperature differences of transverse scans at the (1,0,0.5) and (0,1,0.5) magnetic Bragg peak positions in NaFe_{0.985}Co_{0.015}As single crystal under uniaxial pressure of ~10 MPa. (b) Temperature dependence of the AF peak intensity at $\mathbf{Q}_1 = (1,0,0.5)$ under uniaxial pressure with vertical dashed lines indicating $T_c = 14$ K, $T_N = 31$ K, and $T_s = 40$ K. (c) Neutron spin resonance modes at $\mathbf{Q}_1 = (1,0,0.5)$ and $\mathbf{Q}_2 = (0,1,0.5)$ are obtained by taking temperature differences of the constant- \mathbf{Q} scans below and above T_c in uniaxial pressure partially detwinned sample. (d) Neutron spin resonance modes in pressure released a sample obtained using the same sample and the same sample holder with the same spectrometer setup as in (c). The similar intensity of the resonance at \mathbf{Q}_1 and \mathbf{Q}_1 indicate that the sample becomes nearly 100% twinned.

rather difficult to precisely determine the magnitude of the actual uniaxial strain on the sample). Similar to previous neutron scattering works [39], we align the sample in the $[1,0,0.5] \times [0,1,0.5]$ scattering plane. In such a scattering geometry, we are able to measure the static magnetic order and excitations at both $\mathbf{Q}_1 = (1,0,0.5)$ and $\mathbf{Q}_2 = (0,1,0.5)$.

Figure 2(a) shows background subtracted elastic transverse scans across Q_1 and Q_2 [45]. By comparing the intensities between these two positions, we estimate that the sample has a detwinning ratio $\eta = [I(1,0) - I(0,1)]/[I(1,0) + I(0,1)] \approx$ 62.4%. Temperature dependence of the magnetic order parameter measured at \mathbf{Q}_1 reveals $T_N \approx 31$ K and a suppression of the static AF order below $T_c \approx 14$ K [Fig. 2(b)]. Figure 2(c) shows the temperature difference of the energy scans at Q_1 and \mathbf{Q}_2 below and above T_c . Similar to the results in the twinned sample [12], two neutron spin resonance modes are found at $E_{r1} \approx 3.5$ meV and $E_{r2} \approx 6$ meV, respectively, and a spin gap opens below E = 3 meV in the superconducting state. Moreover, intensities for both resonance modes are higher at the AF position \mathbf{Q}_1 than at \mathbf{Q}_2 . This is different from our previous data obtained on PUMA [40], which is likely due to the improved detwinning ratio in the present study. To further confirm that such a difference is induced by uniaxial strain, we released the uniaxial pressure and carried out the same energy scans on the same sample under the same experiment setup. Figure 2(d) shows the temperature difference of the energy scans upon releasing the uniaxial pressure. As expected, the

FIG. 3. (a) Sum of neutron spin resonance mode intensities at \mathbf{Q}_1 and \mathbf{Q}_2 in the partially detwinned and pressure released sample separately. (b) The ratio between the temperature difference of constant- \mathbf{Q} scans (below and above T_c) at \mathbf{Q}_1 and \mathbf{Q}_2 in the partially detwinned sample. Points with large error bars around E = 4.5 meV are not shown. The open circle labels the detwinning ratio measured from the static AF order. (c) Temperature dependence of background subtracted spin excitations at $E_{r2} = 6.5$ meV at \mathbf{Q}_1 and \mathbf{Q}_2 in the partially detwinned sample [45]. (d) The corresponding ratio of temperature dependence of spin excitations at $E_{r2} = 6.5$ meV between \mathbf{Q}_1 and \mathbf{Q}_2 . T_c , T_N , and $T^* > T_s$ are labeled with dashed lines in (c) and (d).

sample goes back to the twinned state, and there are no observable differences of both resonance modes between Q_1 and Q_2 .

Since our experiments are carried out using the same spectrometer setup on the same unaxial pressure detwinned and twinned (pressure released) sample with the same sample holder, we are able to compare the effect of uniaxial pressure on the double resonances directly. Figure 3(a) shows the intensity sum of the double resonances at Q_1 and Q_2 in the partially detwinned sample and twinned sample. We find that the resonance intensities are identical in these two cases, thus indicating that the intensity gain at Q_1 in the detwinned sample comes from the intensity loss at Q_2 . Figure 3(b) shows the ratio of resonance intensities between Q_1 and Q_2 in the partially detwinned sample. Since the intensity ratios for both resonance modes agree well with the detwinning ratio obtained using magnetic Bragg peaks [Fig. 2(a)], we conclude that neutron spin resonance modes in this system only appear at \mathbf{Q}_1 in a 100% detwinned sample.

Figure 3(c) shows background subtracted temperature dependence of the second resonance ($E_{r2} = 6.5 \text{ meV}$) measured at \mathbf{Q}_1 and \mathbf{Q}_2 under uniaxial pressure [45]. The intensity kink at T_N and strong increase below T_c at both wave vectors agree with previous INS results in the twinned sample [12]. At temperatures well above T_c , T_N , and T_s , magnetic scattering at \mathbf{Q}_1 and \mathbf{Q}_2 are identical and independent of the applied uniaxial pressure. On cooling to 80 K ($>T_s$), we start to see higher magnetic scattering at \mathbf{Q}_1 , consistent with earlier work

FIG. 4. Temperature differences of constant energy scans at \mathbf{Q}_1 and \mathbf{Q}_2 between 1.5 and 21 K at (a) $E_{r1} = 3.75$ meV, (b) $E_{r2} = 6.5$ meV in the partially detwinned sample, and (c) $E_{r2} = 6.5$ meV in the pressure released sample. (d) Comparison of the sum of the magnetic scattering at \mathbf{Q}_1 and \mathbf{Q}_2 for the partially detwinned and twinned sample.

on other iron pnictide superconductors suggesting the presence of a spin nematic phase [39,46]. The intensity ratio between \mathbf{Q}_1 and \mathbf{Q}_2 at $E_{r2} = 6.5$ meV is shown in Fig. 3(d). The clear spin excitation anisotropy above T_s is likely due to the applied uniaxial pressure as discussed in Refs. [47,48]. As a function of decreasing temperature, the magnetic scattering anisotropy starts to build up below T*, saturates at temperatures slightly below T_N , and shows no anomaly across T_c .

Figures 4(a) and 4(b) summarize the wave-vector dependence of the double resonances in the partially detwinned sample at \mathbf{Q}_1 and \mathbf{Q}_2 . The intensity ratios between \mathbf{Q}_1 and \mathbf{Q}_2 at both resonance energies $E_{r1} \approx 3.75$ meV and $E_{r2} \approx 6.5$ meV are consistent with the detwinning ratio at the elastic position. When the uniaxial pressure is released, we find no difference between \mathbf{Q}_1 and \mathbf{Q}_2 at the resonance energy and the sample goes back to the twinned state [Fig. 4(c)]. Figure 4(d) compares the sum of the resonance intensity at \mathbf{Q}_1 and \mathbf{Q}_2 for the pressured (solid diamonds) and pressure-free case (open circles). To within the statistics of our measurements, we find them to be identical.

Several different theories have been proposed to understand the double resonances [28–30]. In the theory of the coexisting static AF order and superconductivity [28,29], the AF order leads to a reconstruction of the Fermi surface, which gives rise to different resonance energies E_{r1} and E_{r2} at wave vectors \mathbf{Q}_1 and \mathbf{Q}_2 , respectively. In a twinned sample, double resonances should appear at both \mathbf{Q}_1 and \mathbf{Q}_2 . Since E_{r1} is expected to be related to the static AF order and its associated spin waves, it should only appear at the AF ordering wave vector \mathbf{Q}_1 in a detwinned sample, while E_{r2} associated with the Fermi surface nesting should appear at both \mathbf{Q}_1 and \mathbf{Q}_2 [28,29]. However, the simultaneous enhancement (suppression) of both resonance peaks at \mathbf{Q}_1 (\mathbf{Q}_2) observed in our experiment for a detwinned sample appears to rule out this theory. This is consistent with polarized inelastic neutron scattering experiments, which reveal that low-energy spin waves (E < 10 meV) in NaFeAs are dominated by *c*-axis polarized excitations [49], while the neutron spin resonance at E_{r1} has both *a*-axis and *c*-axis polarized components [50].

Alternatively, the double resonances may be associated with the gap anisotropy induced by the strong orbital-selective superconducting pairing [30]. In the superconducting phase of the detwinned $NaFe_{0.985}Co_{0.015}As$, the splitting between the d_{xz} and d_{yz} orbitals strongly modifies the Fermi surface nesting condition, as shown in Fig. 1(c). As a consequence, the superconducting gaps associated with different orbitals are also different, i.e., $\Delta_{xz} \neq \Delta_{yz} \neq \Delta_{xy}$. Since the Fermi surfaces have mixed orbital character, such an orbital dependent pairing will give rise to gap anisotropy along the Fermi surfaces. It will also make the resonance energies very different between the intraorbital $(d_{yz}-d_{yz})$ and interorbital $(d_{yz}-d_{xy/xz})$ scatterings, although both scatterings may take place at the same wave vector. Therefore, it is expected that these intraand interorbital scatterings with different energy scales lead to two spin resonance peaks at Q_1 , just as observed in our experiment.

In conclusion, our INS experiments on partially detwinned NaFe_{0.985}Co_{0.015}As shows that neutron spin resonance in this system only appears at the AF wave vector $\mathbf{Q}_{AF} = (1,0)$. We connect our observations with the anisotropic band shifting below T_s in NaFe_{1-x}Co_xAs superconductors. The d_{yz}/d_{xz} orbital degeneration breaks at T_s (or higher temperatures under uniaxial pressure), and bands with dominant d_{yz} orbital character shift up in energy and have better nesting conditions [31,32]. Our analysis agrees with such band structure change and indicates neutron spin resonance in NaFe_{0.985}Co_{0.015}As reveals a strong orbital dependent superconducting pairing enhanced by the reconstruction of the band structure below T_s , in which the scatterings associated with the d_{yz} orbital play a crucial role. These results suggest that intraorbital quasiparticle scattering of the d_{yz} - d_{yz} orbitals are important for superconductivity, similar to magnetic scattering of the $LiFe_{1-x}Co_xAs$ family of materials [43].
