Received 28 April 2008; published 23 July 2008

We use thermodynamic and neutron-scattering measurements to study the effect of oxygen annealing on the superconductivity and magnetism in \( Pr_{0.88}LaCe_{0.12}CuO_4-\delta \). Although the transition temperature \( T_c \) measured by susceptibility and superconducting coherence length increases smoothly with gradual oxygen removal from the annealing process, bulk superconductivity, marked by a specific-heat anomaly at \( T_c \) and the presence of a neutron magnetic resonance, only appears abruptly when \( T_c \) is close to the largest value. These results suggest that the effect of oxygen annealing must first be determined in order to establish a Ce doping dependence of antiferromagnetism and superconductivity phase diagram for electron-doped copper oxides.

I. INTRODUCTION

High transition temperature (high-\( T_c \)) superconductivity occurs in copper oxides when sufficient holes or electrons are doped into the \( CuO_2 \) planes of their antiferromagnetic (AF) parent compounds. To understand the relationship between antiferromagnetism and superconductivity, it is essential to determine the doping evolution of the magnetic phase diagram. For hole-doped \( La_{2-x}Sr_xCuO_4 \) (LSCO), the static long-range AF order is suppressed and superconductivity emerges for a critical Sr doping level of \( x > 0.06 \).¹² In the case of electron-doped copper oxides such as \( Nd_{2-x}Ce_xCuO_4-\delta \) (NCCO), \( Pr_{2-x}Ce_xCuO_4-\delta \) (PCCO), and \( Pr_{1-x}LaCe_xCuO_4-\delta \) (PLCCO), the long-range AF phase appears to extend over a wide Ce doping range (\( x \approx 0.1 \)) and coexist with superconductivity.³⁴ In particular, transport and optical measurements on PCCO thin films revealed an AF quantum critical point (QCP) inside the superconducting dome at \( x = 0.16 \), where the coexisting AF and superconducting phase \( (0.13 \leq x \leq 0.16) \) is separated from the pure superconducting phase \( (x > 0.16) \). These results are consistent with the presence of a normal-state gap (induced by the static/fluxuating AF order) at \( x = 0.15 \) on NCCO revealed by angle-resolved photoemission spectroscopy and optical measurements.⁵ However, a recent neutron-scattering experiment on NCCO suggests that genuine long-range AF order and superconductivity do not coexist, and the QCP separating the pure AF and superconducting phases lies just before the superconducting dome at \( x \approx 0.13 \).¹⁰ Therefore, the true AF phase in NCCO extends only to \( x = 0.13 \) and the phase diagrams of electron-doped materials are much different from previous work.³⁷ as illustrated in the inset of Fig. 1(a).

Unlike their hole-doped counterparts, electron-doped materials exhibit no superconductivity in the as-grown state until they are annealed in an oxygen-poor environment to remove a small amount of oxygen.¹¹,¹² Although three-dimensional (3D) static long-range AF order is observed to coexist with superconductivity in annealed NCCO for \( 0.13 \leq x \leq 0.17 \),³⁴ the existence of static AF order has been argued as an artifact induced by the inhomogeneous annealing process for this family of materials.¹⁰ Therefore, to understand the microscopic mechanism of the annealing process and its impact on bulk superconductivity,¹³⁻¹⁵ one must choose electron-doped materials that can be annealed continuously into pure superconductors without coexisting static AF order.¹⁶,¹⁷ Our prior elastic neutron-scattering measurements showed that electron-doped PLCCO \( (x = 0.12) \) is ideal for this purpose.¹⁸

In this paper, we present systematic specific-heat and neutron-scattering measurements designed to study the annealing effect on PLCCO \( (x = 0.12) \) as the system is tuned from an as-grown antiferromagnet to a pure superconductor \( (T_c=27 \text{ K}) \) without static AF order. Although magnetic susceptibility and elastic neutron-scattering measurements suggest a gradually increasing \( T_c \) (Fig. 1) and decreasing \( T_N \), respectively, with increasing oxygen loss,¹⁸ we find that the bulk superconductivity and neutron magnetic resonance occur only for PLCCO samples with the largest \( T_c's \). Our results thus suggest that the neutron-scattering results determined using NCCO single crystals without systematically studying the oxygen annealing effect is unreliable,¹⁰ and the phase diagram obtained on PCCO films with properly tuned optimal superconductivity reveals the intrinsic properties of the electron-doped materials.

II. EXPERIMENT

We grew PLCCO \( (x = 0.12) \) single crystals by the traveling-solvent floating-zone method.¹⁸ The as-grown non-superconducting PLCCO exhibits static AF order with \( T_N \sim 200 \text{ K} \).¹⁸ The annealing process is a dynamic process of removing oxygen, and the final oxygen content is determined by the temperature, the oxygen partial pressure, and the annealing time.¹⁶,¹⁷ Instead of annealing in argon gas,⁴ we use high-vacuum annealing to reduce the oxygen partial pressure and increase the dynamic range of temperature.¹⁶
FIG. 1. (Color online) (a) $T_c$ (90%) vs $\Delta$ for the same sample annealed at various temperatures in vacuum. $T_c$ (90%) is defined as the temperature where the susceptibility loses 90% of its value at 2 K. Inset shows the schematic Ce content dependence of $T_c$ and $T_x$ (b) Magnetic susceptibility of PLCCO samples with $\delta$=0.034, 0.038, 0.042, 0.047, 0.053, 0.066, 0.092 from left to right of the figure. (c) and (d) are the [0.5,0.5,1] and $[H,H,2.2]$ scans through the impurity phase $R_2O_3$ peak position. The scattering intensity is normalized to a measured phonon at $Q=\pm(0.1,-0.1,0)$ and $T=80$ K (Ref. 26).

Figure 1(a) shows $T_c$ vs oxygen loss $\Delta$ obtained for one PLCCO crystal (~1 gram) using a thermogravimetric analyzer (TGA) from 800 to 880 °C. Data points correspond to sequential days of annealing. Magnetic susceptibility measurements in Fig. 1(b) show that the superconducting volume fraction becomes larger than 90% for samples with $T_x\approx 20$ K. Our neutron-scattering experiments were carried out on the HB-1 and BT-9 thermal triple-axis spectrometers at the high-flux isotope reactor, Oak Ridge National Laboratory and NIST Center for Neutron Research, respectively. We define the wave vector $Q$ at $(q_x,q_y,q_z)$ as $(H,K,L)={(q_x,2\pi,q_y,2\pi,q_z,2\pi)}$ reciprocal lattice unit (r.l.u.) in the tetragonal unit cell of PLCCO (space group $I4/mmm$, $a=b=3.98$ Å, and $c=12.28$ Å). For the specific-heat measurements, we used a commercial calibrated calorimeter with a 14 T physical property measurement system and a $^3$He insert capable of reaching 0.4 K.

Recently, we suggested that the annealing process in electron-doped cuprates mainly involves repairing Cu deficiencies in the as-grown sample, which suppress local superconductivity and induces staggered AF moments extending over several unit cells much like the effect of nonmagnetic Zn impurities.\textsuperscript{20,21} As a consequence, the band filling and band parameters are not much affected by the annealing process.\textsuperscript{14,22} Assuming that the annealing process indeed fills the copper vacancies by producing thin slabs of the anion-deficient fluorite impurity phase $R_2O_3$ ($R=Pr,La,Ce$) through $R_2Cu_xO_{4-δ} = (1-f)(R_2CuO_4) + f(R_2O_3) + \frac{1}{4} \delta \pm (\delta + \beta + f(1-\beta))$ where oxygen loss $\Delta = -\delta + \beta + f(1-\beta)$,\textsuperscript{15} the amount of the impurity $R_2O_3$ created during the annealing process should increase with increasing $\Delta$. Figures 1(c) and 1(d) show the [0.5,0.5,1] and $[H,H,2.2]$ scans through the $R_2O_3$ impurity peak position at (0.5,0.5,2.2) respectively.\textsuperscript{23,24} These data reveal that the impurity peaks for the higher $T_c$ samples have a larger peak intensity and narrower peak width along the $L$-axis direction. The volume fraction of the impurity phase increases with increasing $\Delta$. Quantitatively, we estimate that the ratio of impurity contents between the $T_c=27$ K and 21 K samples is about 1.6, meaning that the $T_c=21$ K sample should have 0.75% Cu vacancies if we assume that the $T_c=27$ K PLCCO has no Cu deficiency.\textsuperscript{15}

Although Figs. 1(a) and 1(b) show that the $T_c$ of PLCCO measured by susceptibility increases with increasing $\Delta$, it is unclear when bulk superconductivity first appears in the annealing process. Electronic specific-heat measurements are one way to determine bulk superconductivity. Since the upper critical field $H_{c2}$ of electron-doped superconductors is less than 10 T for $H//c$, the change in the electronic specific heat can be obtained from the difference between specific heats in the superconducting ($H=0$ T) and field-suppressed normal states ($H=10$ T).\textsuperscript{25} Figure 2(a) shows that the superconducting jump decreases rapidly with decreasing $T_c$ and

FIG. 2. (Color online) (a) The subtracted electronic specific heat for four different samples with field $H//c$. A small linear background ($<0.35$ mJ/K$^2$ mole at 30 K) is also subtracted for all the samples. (b) The entropy difference between the superconducting and normal states of three different $T_c$ PLCCO. (c) The temperature dependence of $U_c$ for three different samples. (d) Temperature dependence of $C/T$. (e) $C/T$ vs $T^2$ measured on $He^3$ probe. (f) The residual electronic specific heat $C=\gamma SC/T$ at 0 K and the superconducting electronic specific heat $C=\gamma S(T)/T$ at 0 K.
vanishes for $T_c < 20$ K samples, although the superconducting volume determined by magnetic susceptibility is still large. Figures 2(b) and 2(c) plot the differential entropy $\Delta S$ and the superconducting condensation energy $U_c$ using $\Delta S(T)\propto \int\frac{C(S-T)}{T}dT$, $U_c(T)\propto \int\frac{\Delta S(T')}{T'}dT'$, which further illustrates how fast the bulk superconductivity disappears with decreasing $T_c$. To extract the absolute values of the electronic specific heat, we fit the low-temperature total specific-heat data as $C_{\text{total}}(T) = \gamma_0 + \beta T^2$, where $\beta T^2$ is the lattice contribution and $\gamma_0 T$ represents the electronic contribution. For as-grown PLCCO, the large low-temperature Schottky anomaly prevents an accurate determination of $\gamma_0$. For annealed nonsuperconducting and superconducting samples, we obtain $\gamma_0$ using data in Figs. 2(d) and 2(e) and a measure of the residual superconducting contribution, $\gamma_{\text{SC}}$, using data in Fig. 2(a) with $\Delta C/T(10 \text{ T} - 0 \text{ T})$. The $T_c$ dependences of $\gamma_0$ and $\gamma_{\text{SC}}$ are shown in Fig. 2(f). The nonzero $\gamma_0$ may arise from the residual metallic nonsuperconducting portion of the superconductor. Previous experiments have shown the existence of static 3D AF order coexisting with superconductivity in lower $T_c$ samples. If a low-$T_c$ PLCCO sample is electronically phase-separated into insulating AF ordered, metallic nonsuperconducting, and superconducting regions, one would expect that the residual $\gamma_0$ associated with the nonsuperconducting part of the metallic phase decreases with increasing $U_c(0)$ and volume fraction. In this picture, the annealing process initially weakens the static AF order with almost no change in the metallic phase, as indicated by the reduction in $\gamma_0$ from the as-grown to 650 °C annealed nonsuperconducting states [Fig. 2(f)]. Bulk superconductivity only emerges for PLCCO with $T_c \geq 20$ K. With further annealing, $\gamma_{\text{SC}}$ increases rapidly with increasing $T_c$ and $U_c$ while $\gamma_0$ decreases slowly, suggesting that the enhanced superconductivity with annealing is at the expense of static AF order. For PLCCO samples with $T_c \geq 24$ K, where the static AF order essentially vanishes, the increasing $U_c$ with annealing may be at the expense of the metallic nonsuperconducting phase with a reduction in $\gamma_0$ [Fig. 2(f)].

Figures 3(a) and 3(b) show the magnetic-field dependence of the superconducting specific-heat anomaly for the $T_c=27$ K and 22 K samples, respectively. Figure 3(c) plots the temperature dependence of $H_{c2}$ determined by the middle point of the negative slope region in the specific-heat jump. Using the Helfand-Werthamer formula $H_{c2}(0) = 0.7 \times T_c \times dH_{c2}/dT$, we find the $H_{c2}(0)$ values of 8.5 T, 12 T, and 15 T for $T_c=27$ K, 24 K, and 22 K, respectively. For pure superconducting $T_c=27$ K PLCCO, the in-plane coherence length $\xi(0)$ is about 62 Å in the clean $s$-wave limit, where $H_{c2}(0) = \phi_0/2\pi\xi^2(0)$ and $\phi_0$ is the quantum of flux. For $T_c=24$ K and 22 K samples, $\xi(0)$ decreases to 52 Å and 47 Å, respectively. This is consistent with the expected 0.75% Cu vacancies in the $T_c=21$ K sample, where the average distance between two Cu vacancies is about 50 Å. On the other hand, dynamic spin-spin correlations at $h\omega=1.5$ meV decreases with increasing $T_c$, changing from 200±21 Å to 93±14 Å and 80±10 Å for $T_c=21$ K and $T_N=40$ K, $T_c=23$ K and $T_N=25$ K, and $T_c=24$ K PLCCO, respectively. Therefore, oxygen annealing should affect spin correlations determined by two-axis measurements.

To test if the annealing process also affects the recently discovered magnetic resonance, we carried out neutron-scattering experiments on $T_c=27$ K and $T_c=21$ K samples. Similar to measurements on $T_c=24$ K samples, we isolate the resonance $(E_r)$ by taking the difference of constant-$Q$ scans at $Q=(0.5,0.5,0)$ between the superconducting $(T=6$ K) and normal states $(T=30$ K). The data of constant-$Q$ scans for the $T_c=27$ K and $T_c=21$ K samples are shown in Figs. 4(a) and 4(b), respectively. By fitting the subtracted data with Gaussians, we find $E_r=10.3 \pm 0.38$ meV [Fig. 4(e)] and $E_r=9.3 \pm 0.69$ meV [Fig. 4(d)]. The decreasing energy $E_r$ of the resonance with decreasing $T_c$ is consistent with the reduction of the superconducting gap and the $E_r=5.8\Delta/T_c$ universal plot. Figures 4(e) and 4(f) show constant energy scans near $E_r$ at 6 K and 30 K for these two samples. Comparison of these data...
also reveals that the intensity gain from the normal to superconducting states for the $T_c = 27$ K sample is considerably larger than that of the $T_c = 21$ K sample in agreement with our conclusions regarding bulk superconductivity based on thermodynamic measurements.

III. DISCUSSIONS AND CONCLUSIONS

The effect of annealing on superconductivity and magnetism in PLCCO appears to be similar to that of Zn doping in the electron-doped superconductor NCCO, where a few per-

FIG. 4. (Color online) Constant $Q$ scans at $Q=(0.5,0.5,0)$ at $T=6$ K and 30 K for (a) $T_c = 27$ K and (b) $T_c = 21$ K PLCCO. The small peak at $\hbar \omega = 6$ meV is the Pr crystal field from the “impurity” $R_2O_3$ phase which is not present in the as-grown PLCCO (Ref. 19). The corresponding differences between 6 K and 30 K are shown in (c) and (d), indicating resonance peaks. (e) and (f) show constant energy scans through $[H,H,0]$ at 6 K and 30 K near the resonance energies for these two samples.
cent of Zn impurities (Cu vacancies in the as-grown sample) can completely suppress superconductivity.\textsuperscript{20,21} In addition, the increasing $\gamma_0$ with decreasing $T_c$ in PLCCO [Fig. 20(f)] is also similar to the Zn doping dependence of $\gamma_0$ in YBCO.\textsuperscript{32} Since both the superconducting coherence length and spin-spin correlation length are strongly affected by the oxygen annealing process, these results call into question the suggestion that there is no genuine coexisting AF and superconducting phase and the QCP occurs just before the superconducting dome at $x \approx 0.13$.\textsuperscript{10} In our view, any attempt to establish the Ce doping evolution of the AF to superconducting phase transition on electron-doped materials must begin by systematically determining the oxygen annealing effect at different Ce dopings.\textsuperscript{33} This implies that one must examine the electron-doped superconductors with the highest $T_c$ at a fixed Ce doping as in the thin-film PCCO case to determine their intrinsic electronic properties.\textsuperscript{5,6}
